

House Price Prediction – Summary Report

Name- Ankita Bhattacharjee

Summary Report on House Price Prediction. This project's goal was to create a machine learning model that could forecast home values using a variety of property attributes. The dataset was examined, cleaned, and made ready for analysis by eliminating duplicate records and managing categorical variables.

Two regression models were trained and assessed: Random Forest Regressor and Linear Regression. The analysis revealed that several factors, including air conditioning, parking availability area and the number of bathrooms, significantly affected home prices.

The Random Forest Regressor outperformed the other models in terms of performance and prediction accuracy. The findings showed that higher market values were typically associated with larger homes with better amenities.

One intriguing finding was that homes in preferred neighborhoods typically cost significantly more than comparable homes in non-preferred neighborhoods.

These results suggest that real estate companies should concentrate on properties with more space and contemporary amenities because these attributes have a significant impact on both buyer demand and property value.
